(Received February 7, 2008)

The ground state property of the alternating spin ladder is studied in the case that the system involves an antiferromagnetic intra-chain interaction as well as two kinds of inter-chain interactions; one is between spins of the same magnitude and the other is between spins with different magnitudes. The calculation has been carried out by the exact diagonalization method. As a consequence of the competition among interactions, the system is revealed to show an interesting variety of phases in the ground state property. Its phase diagram is exhibited in the parameter space of the system. We find that, however small the total amount of the inter-chain interactions is, the ferrimagnetic ground state becomes unstable in a certain region. In this case, which of the ferrimagnetic and the singlet ground state to appear is determined only by the ratio between the inter-chain interactions regardless of their total amount. The nature of two phases appearing in the singlet region of the phase diagram and the type of the phase transition between them are also discussed. The results are ensured by comparing with those of obtained in other models which are contained in our model as special limiting cases.

§1. Introduction

The prediction given by Haldane in his distinguished works^{1,2)} has had a profound influence on the research in the low-dimensional spin systems during the following decades. In the subsequent decade, extensive studies on this issue had been developed by means of various theoretical approaches as well as computational ones. As a result, the prediction seems now to be entirely agreed with and has received wide recognition.^{3,4)} This prediction states that in the one-dimensional antiferromagnetic Heisenberg model, qualitative properties of the ground state depend entirely on whether the system is constructed of half-integral spins or integral spins. The energy gap, named Haldane gap, does exist between the ground state and the first excited state in the case of integral

* e-mail: atsuo@grad.ap.kagu.sut.ac.jp

spin, while the energy gap never appears in the case of half-integral spin. During recent years in this decade, the current interest on this issue has extended to a various kinds of low-dimensional spin systems; mixed spin chains with various arrangements of spins and bonds as well as spin-ladder systems of various kind. This renewal of the interest on this matter owes partly to the advance of experimental techniques and the recent technical development in the material science; the discoveries and experimental realizations of such various kinds of low-dimensional systems in recent years have attracted widespread attention beyond its own research field and have inspired accumulating efforts and activities in this field.

Among these low-dimensional spin systems, an alternating spin chain with antiferromagnetic nearest neighbor interactions have provided rich subjects in the field from both theoretical and experimental aspects.^{5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19)} The spin arrangement of this alternating spin chain is such that the constituent spins of different magnitude align alternately along the chain. Because of this spin arrangement and the antiferromagnetic nearest neighbor interaction, the application of the Lieb-Mattis theorem²⁰⁾ leads to that the total spin moment of this chain has a non-zero value in its ground state; so-called “quantum ferrimagnetic state” is realized as the ground state. It is also shown by the spin wave theory that this alternating spin chain has two kinds of excitations, one is ferromagnetic and the other antiferromagnetic; because of these excitations thermodynamic properties of the alternating spin chain shows ferromagnetic-antiferromagnetic crossover.^{13, 14, 15, 16)}

From experimental side, on the other hand, several kinds of the alternating spin chains have been found in actual materials recently,^{17, 18, 19)} and detailed studies on their lattice structures and their magnetic properties have been developed extensively. For example, the compound, MnCu-pbaOH that is $\text{MnCu}(\text{pbaOH})(\text{H}_2\text{O})_3$ with pbaOH = 2-hydroxy-1,3-propylenebis (oxamato), has such crystal structure that Mn^{2+} ($S = \frac{5}{2}$) and Cu^{2+} ($S = \frac{1}{2}$) ions bridged by oxamato groups are forming antiferromagnetic alternating spin chain along the b -axis, named by $\text{Mn}^{\text{II}}\text{Cu}^{\text{II}}$ bimetallic chain.¹⁷⁾ Comparing with the intra-chain interaction, the inter-chain exchange interactions between the nearest spins (Mn-Mn and Cu-Cu) seems to be rather weak. Therefore we may regard this compound as an assembly of $\frac{1}{2}$ - $\frac{5}{2}$ -spin alternating chains which are interacting weakly each other so that we can expect for the ground state of this compound to be ferromagnetic. In fact, the results of magnetic measurements on this compound are consistent with this view.¹⁷⁾ So we may list this $\text{Mn}^{\text{II}}\text{Cu}^{\text{II}}$ bimetallic chain as an example of the actual realization of a “quantum ferrimagnet”. It should be noted, however, that this kind of antiferromagnetic bimetallic chains realized in actual compounds does not always exhibit the ferrimagnetic character. There exist, in fact, another family compound which contains the same $\text{Mn}^{\text{II}}\text{Cu}^{\text{II}}$ bimetallic chains, but it has nevertheless a non-magnetic ground state; MnCu-pba that is $\text{MnCu}(\text{pba})(\text{H}_2\text{O})_3 \cdot 2\text{H}_2\text{O}$ with pba = 1,3-propylenebis (oxamato) is just the case.¹⁷⁾ There is not a great difference between crystal structure of MnCu-pbaOH and MnCu-pba except for relative positions of the chains along the a -axis. In the MnCu-pba

as compared with the MnCu-pbaOH, every chains make a slight shift along the b -axis (the chain direction) relatively to their respective neighboring chains. As a consequence of this shift, the inter-chain interaction between Mn-Cu in the MnCu-pba may become weak compared with that in the MnCu-pbaOH, and the inter-chain interaction between Mn-Mn and Cu-Cu may become strong at the same time. These considerations, therefore, lead us to an idea that the competition between two kinds of inter-chain interactions play an important roll in the determination of magnetic properties of these compounds at low temperatures.

The aim of this paper is to clarify the magnetic character of such materials containing spin alternating chains as stated above. Actually in this paper, for the sake of simplicity, we investigate the ground state properties of a two-leg ladder system composed of alternating spin chains, called by alternating spin ladder. There, we introduce two kinds of inter-chain interactions, one is between same kind of spin and the other between different kinds of spins. Then we examine the effect of the competition among the interactions on the properties of the ground states, and make up its phase diagram by the use of numerical method, the exact diagonalization using the Lanczos method.

In the next section, we present the model Hamiltonian and explain some of results derived from it by simple considerations before we undergo the numerical analysis. The discussion is also made comparing our model with other ones studied by others previously. In §3, are shown the results derived numerically with this model Hamiltonian. In §4, we exhibit the resultant phase diagram for the ground state of the alternating spin ladder and discuss what it means. Finally, the results are summarized in §5.

§2. The Model

Here we present the model Hamiltonian for a spin ladder composed of the same kind of alternating spin chains which are interacting by two kinds of inter-chain interactions. For the sake of simplicity, the magnitudes of spins constructing the constituent alternating spin chain are taken actually as $S = \frac{1}{2}$ and 1, since the properties of the alternating spin chain is qualitatively independent of the magnitudes of spins.⁸⁾ The Hamiltonian is given as follows;

$$\begin{aligned}
 H = & J \sum_{j=1}^2 \sum_{i=1}^{\frac{N}{2}} \mathbf{S}_{j,i} \cdot \mathbf{S}_{j,i+1} + J_0(1 - \delta) \sum_{i=1}^{\frac{N}{2}} \mathbf{S}_{1,i} \cdot \mathbf{S}_{2,i} \\
 & + J_0(1 + \delta) \sum_{i=1}^{\frac{N}{2}} \mathbf{S}_{1,i} \cdot \mathbf{S}_{2,i+1},
 \end{aligned} \tag{2.1}$$

where index j specifies the chain number and $\mathbf{S}_{j,2i-1}$ and $\mathbf{S}_{j,2i}$ denote spins of magnitude $\frac{1}{2}$ and 1 on each chain, respectively. Here N is the total number of spins in this system, and is taken as a multiple of four because of a periodic boundary condition ($\mathbf{S}_{j,\frac{N}{2}+1} = \mathbf{S}_{j,1}$) imposed in this paper. J represents the intra-chain interaction in each alternating spin chain. $J_0(1 - \delta)$ and $J_0(1 + \delta)$ are the inter-chain interactions between the chains; the former represents interaction between the same

kind of spins ($1-1$ and $\frac{1}{2}-\frac{1}{2}$) and the latter between different kinds of spins ($1-\frac{1}{2}$), respectively. A schematic representation of the Hamiltonian is given in Fig.1(a). Since we are to investigate the effect of the competition among the antiferromagnetic interactions on the ground state properties, we restrict the parameters J_0 , J and δ to the following region; $J_0 > 0$, $J > 0$ and $1 \geq \delta \geq -1$. Here we should note that changing the value of δ corresponds to the relative shift between chains along the chain direction.

Even though we restrict the parameter region as stated above, the Hamiltonian still maps to various models if we change the parameters. In our parameter region, there exists such a region that we can apply there the Lieb-Mattis theorem to the system and are able to find the total spin momentum of the ground state. For each case of $\delta = 1$ and -1 , the Hamiltonian contains only one kind of inter-chain interaction and is free from the frustration so that we can use the Lieb-Mattis theorem to investigate the ground state properties: As a result, we find that the ground state is a singlet state when $\delta = -1$ and, on the other hand, the ground state becomes a quantum ferrimagnetic state having a total spin moment ($= \frac{N}{4}$) when $\delta = 1$. From these results for two limiting cases ($\delta = 1$ and -1), therefore, it is easy to understand that the phase transition between the singlet state and the quantum ferrimagnetic state should occur between $\delta = 1$ and $\delta = -1$ for any value of the ratio J_0/J .

Further, we can show another exact result about the ground state of the alternating spin ladder under a certain constraint on the parameters; when $J_0(1+\delta) = 2J$ with $J_0 \geq 3J$, the exact ground state is a dimer state which is depicted in Fig.2(a) by means of the valence-bond-solid picture. The proof can be made almost in the same way as Shastry and Sutherland have done:²¹⁾ In the case of $J_0(1+\delta) = 2J$, the Hamiltonian of the alternating spin ladder can be rewritten as

$$H = \sum_{i=1}^{\frac{N}{2}} \{ J_0(1-\delta) \mathbf{S}_{1,i} \cdot \mathbf{S}_{1,i+1} + J \mathbf{S}_{1,i} \cdot (\mathbf{S}_{1,i+1} + \mathbf{S}_{2,i+1}) + J(\mathbf{S}_{1,i} + \mathbf{S}_{2,i}) \cdot \mathbf{S}_{2,i+1} \}. \quad (2.2)$$

We define the dimer state $|\psi_{\text{dimer}}\rangle$ as $|\psi_{\text{dimer}}\rangle = |[1, 2]_1\rangle |[1, 2]_2\rangle \cdots |[1, 2]_{\frac{N}{2}}\rangle$, where $|[1, 2]_i\rangle$ denotes a singlet state constructed from $\mathbf{S}_{1,i}$ and $\mathbf{S}_{2,i}$. Then $|\psi_{\text{dimer}}\rangle$ can be shown to be the eigen state of the Hamiltonian;

$$H|\psi_{\text{dimer}}\rangle = -\frac{1}{16} J_0(1-\delta)N|\psi_{\text{dimer}}\rangle. \quad (2.3)$$

When $J_0 \geq 3J$, on the other hand, by applying the Rayleigh-Ritz variational principle we can show that $\langle \psi_G | H | \psi_G \rangle \geq -\frac{1}{16} J_0(1-\delta)N$. (Here $|\psi_G\rangle$ is the ground state of the Hamiltonian.) This proves that the dimer state $|\psi_{\text{dimer}}\rangle$ is the exact ground state of the system.

Since we notice that our Hamiltonian is equivalent to that of the $\text{spin-}\frac{1}{2}\text{-}\frac{1}{2}\text{-}1\text{-}1$ chain^{22, 23)} with a next-nearest-neighbor (N-N-N) interaction J as illustrated in Fig.1(b), it is worthwhile to refer to something relating with this chain. Here the $\text{spin-}\frac{1}{2}\text{-}\frac{1}{2}\text{-}1\text{-}1$ chain means an one-dimensional

antiferromagnetic chain where two $S = \frac{1}{2}$ and two $S = 1$ spins are arranged alternately. This spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain can be visualized if we cut off the bond J ($J \rightarrow 0$) in Fig.1(b). This chain without the N-N-N interaction has been studied extensively by Tonegawa *et al.*^{22,23)} and several results about its ground state had been obtained already. In their works, it was shown that a phase transition between two phases of the ground state of the chain is brought about by the introduction of the bond alternation between the nearest-neighbor antiferromagnetic interactions. They found also that this phase transition was a quantum phase transition between two different kinds of singlet phases which are represented schematically in Fig.2(a) and 2(b) by means of the valence-bond-solid picture. Our alternating spin ladder maps onto this bond-alternating spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain if J_0/J approaches to infinity ($J \rightarrow 0$ equivalently). The bond-alternation in the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain, furthermore, corresponds to the variation of δ in our model. In our spin ladder, therefore, we reasonably expect for these singlet phases of the ground state to appear, and can expect that the same type of phase transition between these singlet phases will occur at a certain value of δ in the parameter region where the ratio J_0/J is large enough. After the numerical calculation, it is found that the result is really the case.

§3. Numerical Results

In order to clarify the ground state properties of the alternating spin ladder, we make a numerical study of the system by means of the exact diagonalization method exploiting the Lanczos technique.²⁴⁾ Because of the restriction of our computational environments, the calculation has been carried out for the system size of $N = 8, 12, 16$, and 20 .

3.1 Case of small J_0/J

The system in this parameter region is regarded as a composite of two ferrimagnetic chains interacting weakly each other via two kinds of the inter-chain interactions. As stated in the previous section, for case of $\delta = 1$ and -1 , we know that the ground state becomes a quantum ferrimagnetic state and a singlet state, respectively. Thus there should be a phase transition of the ground state at $\delta = \delta_f$; the ground state is the quantum ferrimagnetic state for $\delta > \delta_f$, and is the singlet state for $\delta < \delta_f$. This is revealed by calculating the δ -dependence of the energy gap between the ground state and the first excited state. The result in the case of $J_0/J = 0.01$ is shown in Fig.3. Since the energy gap in the singlet state is proportional to δ , the transition point δ_f can be determined easily by the least square method; for $N = 20$, $\delta_f = 0.21557$ which is only 0.5 % smaller than one for $N = 16$, so that it would be close to the bulk limit. The phase transition between the singlet state and the ferrimagnetic state is of the first order, because the total spin of the system is found to change from zero to $\frac{N}{4}$ as δ goes from the region of $\delta < \delta_f$ into the region of $\delta > \delta_f$.

From additional calculations, we find the value of δ_f not to be sensitive to the value of J_0/J as far as $J_0/J \lesssim 0.7$; that is, in this region of J_0/J , the appearance of the ferrimagnetism depends scarcely

on the ratio of the total amount of the inter-chain interactions to the intra-chain interaction but does on the ratio of one kind of inter-chain interaction to the other. As a result, the ferrimagnetism disappears for $\delta < \delta_f$ however weak the inter-chain interaction is.

Because the total spin moment of each ferrimagnetic chain, $\langle (\sum_{i=1}^{\frac{N}{2}} \mathbf{S}_{j,i})^2 \rangle$ ($j = 1, 2$), was confirmed to be close to $\frac{N}{8}$ in whole region of δ , we should regard the energy gap in $\delta < \delta_f$ as the singlet-triplet gap of a composite of two giant spins which come from respective ferrimagnetic chains. Although such a state is far from the dimer state which is described in §2, we would like to call the region of these states as the dimer phase for convenience.

3.2 Case of large J_0/J

In the limit of $J \rightarrow 0$, our alternating spin ladder becomes identical to the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain which has been studied extensively by Tonegawa *et al.*^{22,23)} Then, in the parameter region of large J_0/J , we can guess the phenomena in our system by utilizing the knowledge of the phenomena in the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain. This confirmation, furthermore, provides a justification for numerical results obtained in our system. One of the important results in the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain is the existence of the quantum phase transition between two types of singlet states, namely the dimer state and VBS state which are usually depicted by the diagrams in Fig.2(a) and 2(b), respectively.^{22,23)} In the case of large J_0/J in our system, therefore, we expect reasonably that the same kind of the quantum phase transition will also occur at an appropriate value of $\delta = \delta_c$. Tonegawa *et al.* showed that the energy gap between the ground state and the first excited state of their chain goes to zero at this transition point.

Keeping this knowledge in mind, let us look up the calculated energy gap as functions of δ for $J_0/J = 5.0$ with $N = 8, 12$, and 16 shown in Fig.4. We see that the transition point between the singlet and the ferrimagnetic state moves toward right ($\delta_f = 0.87005$) comparing with the case of $J_0/J = 0.01$. Among of all, however, we notice that there is a great difference between this result and that for $J_0/J = 0.01$ in Fig.3; that is, the existence of a minimum in the energy gap. From the knowledge of the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain, we should consider this minimum signifies that the same type of quantum phase transition occurs as has appeared in the chain, although our minimum value is not zero. This non-zero value of the minimum in the energy gap is due to the finiteness of the system size. We can show, in fact, that the minimum value in the energy gap goes to zero as N goes to infinity: We employ such a linear scaling function in $1/N$ as

$$E_{gap}(N)/J = E_{gap}/J + \frac{a}{N} \quad (3.1)$$

where a is a constant of proportionality, $E_{gap}(N)$ denotes the minimum value of the energy gap for the system size N and E_{gap} gives the energy gap in the bulk limit. By using data of $E_{gap}(N)$ ($N = 8, 12$, and 16) for several values of J_0/J , we extrapolate the energy gap $E_{gap}(N)$ at $\delta = \delta_c$ to the bulk limit ($1/N \rightarrow 0$). The results are illustrated in Fig.5. In this way, we ensure that the

thermodynamic limit of the energy gap is really vanishing at $\delta = \delta_c$ and, at the same time, that the value of δ_c approaches to -0.129 ± 0.001 as J_0/J increases. This value of δ_c is consistent with the result calculated by Tonegawa *et al.* in their chain. The property of the singlet phase in the region of $\delta < \delta_c$ for each J_0/J can be guessed as dimer like because the region is continuously connected to the exact dimer line $J_0(1 + \delta) = 2J$ for $J_0 \geq 3J$. The singlet phase in this region, therefore, should be call as a “dimer phase”.

In order to clarify the nature of a singlet phase whose region is sandwiched between those of the dimer phase and the ferrimagnetic phase, we calculate three kinds of inter-chain spin-spin correlation functions;

$$\omega_{\frac{1}{2}-\frac{1}{2}} = \langle \mathbf{S}_{1,2i-1} \cdot \mathbf{S}_{2,2i-1} \rangle, \quad (3.2)$$

$$\omega_{1-\frac{1}{2}} = \langle \mathbf{S}_{1,2i} \cdot \mathbf{S}_{2,2i-1} \rangle, \quad (3.3)$$

$$\omega_{1-1} = \langle \mathbf{S}_{1,2i} \cdot \mathbf{S}_{2,2i} \rangle, \quad (3.4)$$

where ω 's are inter-chain correlation functions between two spins whose magnitudes are specified by their subscripts. In Fig.6, numerical results for these correlation functions are exhibited as functions of δ for the case of $J_0/J = 5.0$ with $N = 16$. The results shown in Fig.6, therefore, indicate that the singlet ground state in the region $\delta < \delta_c$ is well described by the dimer state while one in the region $\delta_c < \delta < \delta_f$ is done by the VBS state; in other words, the dimer state and the VBS state provide a good trial wave function to the singlet ground state in respective regions. We may, therefore, suitably call the singlet phase in $\delta_c < \delta < \delta_f$ as the VBS phase. We can also see in Fig.6 that rapid changes in correlation functions are occurring around $\delta = \delta_c$. From these analyses, we may surely say that a phase transition between the dimer phase and the VBS phase occurs at $\delta = \delta_c$.

3.3 Case of $J_0/J = 1.5$

First, in Fig.7, we show the δ -dependence of the inter-chain spin-spin correlation functions, $\omega_{\frac{1}{2}-\frac{1}{2}}$, $\omega_{1-\frac{1}{2}}$ and ω_{1-1} calculated for $J_0/J = 1.5$ and $N = 16$. It is noticed in this figure that the region of the VBS phase becomes narrower than that for $J_0/J = 5.0$. The curves in this figure, further, make us feel that the natures of these singlet phases of the ground state for this J_0/J value may not be described suitably by such pictures as the dimer state and the VBS state. Nevertheless, in the characteristic behavior of the curves in this figure, we find a kind of similarity with that in the curves for $J_0/J = 5.0$ in Fig.6. So, even for the case of $J_0/J = 1.5$, we use the terms such as the “dimer phase” and the “VBS phase” for convenience to call these singlet phases of the ground state appearing in the region $\delta < \delta_f$.

In Fig.8, the δ -dependence of the energy gap for $J_0/J = 1.5$ is shown. The curves exhibit their minimum points expectedly at $\delta = \delta_c$, at which the curves for the spin correlation functions in Fig.7 have been observed to make rapid changes. This situation is somewhat similar to one in Fig.4

for large J_0/J . We find, however, that the behavior of the energy gap in Fig.8 differs a bit from one in Fig.4. Especially, there is a sharp minimum in the energy gap about the boundary point between the dimer phase and the VBS phase. Furthermore, we could not extrapolate the value of the energy gap in its minimum to the bulk limit by such a function as given in eq.(3.1). To make clear the size dependence of the energy gap, it will be necessary that we calculate it in much larger system. From additional calculations, the VBS phase is likely to disappear in the region where J_0 is comparable to J (see also the phase diagram in the next section). As a matter of course, the transition point between the ferrimagnetic phase and the singlet phase, δ_f , is observed in Fig.8, and we can read off the value of δ_f to be 0.58310.

§4. Phase Diagram and Discussions

The illustration of δ - J_0/J phase diagram would be helpful to understand the properties of the ground state in our system and the relation between our system and the other spin system. Based on the data shown in the previous section together with additional ones, we make up the δ - J_0/J phase diagram for the ground state properties, which is exhibited in Fig.9. We note that three phases are appearing there; named by “ferrimagnetic phase”, “dimer phase”, and “VBS phase”.

Solid squares in the phase diagram express the points with the coordinates $(\delta_f, J_0/J)$ which are determined by the values of δ_f for given J_0/J ; in the region $\delta > \delta_f$, the total spin moment is not zero so that the ground states are ferrimagnetically ordered states while, for $\delta < \delta_f$, the total spin moment becomes zero so that the ground state becomes non-magnetic.

In the region where the inter-chain interactions are weak, there exists only a phase transition between the ferrimagnetic phase and the dimer phase. There, the ferrimagnetic phase is stable only for $\delta > \delta_f$. From the phase diagram we note also that, as far as $J_0/J \lesssim 0.7$, the value of δ_f is not sensitive to the ratio J_0/J ; that is, which of the ferrimagnetic phase and the dimer phase to be stabilized is determined only by the ratio between the two kinds of inter-chain interactions regardless of their total amount. Although this result is obtained for the alternating spin ladder with constituent spin $S = \frac{1}{2}$ and 1, this seems to be scarcely changed by other choice for the magnitudes of the constituent spins. Then in the case of the $\text{Mn}^{II}\text{Cu}^{II}$ bimetallic chain compound, for example, the ratio of one kind of inter-chain interaction (Mn-Cu) to the other (Mn-Mn and Cu-Cu), is supposed to be an important parameter which determines whether the quantum ferrimagnetic state is stable or not.

In the region of the phase diagram where J_0/J is not small, we notice the appearance of the VBS phase. This phase shares the singlet region with the dimer phase. These phase regions are divided by an assembly of solid and open circles; a solid line connecting the former circles and a broken line connecting the latter ones are drawn for a guide to eyes. The solid circles are points which express δ_c for given J_0/J values at which the energy gaps have their minimum whose values are confirmed to vanish in the bulk limit by extrapolation procedure with the scaling function eq.(3.1).

Open circles, on the other hand, are points determined from the same minimum points but their bulk limits could not be confirmed since the scaling function eq.(3.1) does not fit with our data; this may be due to that our system size is too small for the procedure to work.

We note also that the solid boundary line between the dimer phase and the VBS phase approaches asymptotically to the line $\delta = -0.129$ as J_0/J goes to infinity. This value of δ corresponds to the ratio between the alternating bonds in the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain at which the chain has shown to make a quantum phase transition between the “dimer” ground state and the “VBS” ground state.^{22,23)} Therefore, the result of our calculations is surely consistent with the result revealed in the work of Tonegawa *et al.* by means of a quantum Monte Carlo calculation. We notice, furthermore, that a dot-dashed line whose equation is expressed as $J_0(1 + \delta) = 2J$ (with $J_0 > 3J$) is reasonably embedded in the dimer phase region; on this line, as stated in §2, the dimer state becomes the exact ground state. The ground state may be well described in the region close to this exact dimer line. Therefore, we can understand that, as J_0/J becomes large, such a picture of giant spins as described in the case of small J_0/J may break down eventually.

From all these considerations, we have derived a conclusion that, on the solid portion of the boundary line, a quantum phase transition between the dimer and the VBS ground state occurs as it does in the bond alternating spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain. This conclusion may be claimed safely as far as $J_0/J > 2.5$. For $J_0/J \lesssim 2$, it is not clear yet what kind of phase transition occurs on the broken boundary line consisting of open circles. We, however, guess that the phase transition on the broken line would be of the first order, because we find a similar situation in the bond alternating Heisenberg model with spin $S = 1$ involving the next-nearest-neighbor interaction examined by others.^{25,26)} At present, our assertion on this point is only a conjecture. The confirmation of it requires the calculations in much larger system. We think that the method of the density matrix renormalization group may provide an appropriate means to carry out this calculations.

The properties of our system at finite temperatures, such as the specific heat and the magnetic susceptibility, remain as the matters of further interest in connection with the possibility of the ferromagnetic-antiferromagnetic crossover.

§5. Summary

In order to investigate the ground state property of the alternating spin ladder, we carry out the numerical study of the energy gap and the spin-spin correlation function by using the exact diagonalization method. Here the spin ladder is composed of two alternating spin chains of $S = \frac{1}{2}$ and 1 having an antiferromagnetic intra-chain interaction. Two kinds of antiferromagnetic interactions are introduced between the chains. Through the competition among these interactions, it is revealed that the system provides an interesting variety of phases in the ground state. By piling up the data of calculations, we make up a phase diagram of the ground state in the parameter space δ - J_0/J ; J_0/J is the ratio of the amount of inter-chain interactions to the intra-chain inter-

action, and δ is a measure of the ratio between two kinds of inter-chain interactions. In the case of weak inter-chain interactions ($J_0/J \ll 1$), the ground state is shown to undergo the first order transition between the ferrimagnetic phase and the singlet phase at an appropriate value of $\delta = \delta_f$; $\delta_f = 0.21557$ for $J_0/J = 0.01$. This means that, however weak the inter-chain interactions is, there exists a region of δ where the quantum ferrimagnetic state becomes unstable. In the region of large J_0/J , this first order transition between the ferrimagnetic phase and the singlet phase is observed to occur at much larger value of δ_f compared with the case of small J_0/J , so that the ferrimagnetic state is seen to be destabilized more. Furthermore, we see that the singlet phase is divided into the dimer phase and the VBS phase. The transition between these phases is concluded to be of the second order as shown to be the case in the spin- $\frac{1}{2}$ - $\frac{1}{2}$ -1-1 chain studied by Tonegawa *et al.* Even when J_0/J becomes comparable to one, it seems that the singlet phase region is also divided into a dimer like phase and a VBS like one. We could not clarify the nature of the phase transition between them, at present. We only speculate, however, that the phase transition between them may change its nature from the second order transition to the first order one in this region.

Acknowledgements

The authors would like to thank J. Hosoi, K. Sakai and Dr. M. Yamanaka for helpful discussions and encouragement. The authors appreciate very constructive comments by Dr. Y. Yokoya, Dr. Y. Matsushita and Dr. Y. Suwa. Part of the numerical calculations in this work have been performed using the facilities of the Supercomputer Center, Institute for Solid State Physics, University of Tokyo.

Fig.1

Schematic representation of the Hamiltonian (a) for the alternating spin ladder, and (b) for the same Hamiltonian viewed as the $\text{spin-}\frac{1}{2}\text{-}\frac{1}{2}\text{-}1\text{-}1$ chain with the next-nearest-neighbor-interaction J . Large and small circles represent spins $S = 1$ and $S = \frac{1}{2}$, respectively.

Fig.2

Ground state represented schematically by means of the VBS picture for the $\text{spin-}\frac{1}{2}\text{-}\frac{1}{2}\text{-}1\text{-}1$ chain. (a) is for region of small δ and (b) is for region of large δ . The solid circles represent $S = \frac{1}{2}$ spin. The open circles denote a triplet state made up of two $S = \frac{1}{2}$ spins in the circles. The solid lines represent a singlet state of two $S = \frac{1}{2}$ spins on their ends.

Fig.3

δ -dependence of the energy gap for $N = 8$ (solid circle), $N = 12$ (solid square), $N = 16$ (solid triangle) and $N = 20$ (open circle), in the case of $J_0/J = 0.01$. The δ_f value indicated by an arrow in this figure is that for the case $N = 20$, which is read off as 0.21557.

Fig.4

δ -dependence of the energy gap for $N = 8$ (solid circle), $N = 12$ (solid square) and $N = 16$ (solid triangle), in the case of $J_0/J = 5.0$. The value of δ_f , 0.87005, indicated by an arrow is that for $N = 16$, and the value of δ_c indicated there is that for bulk limit ensured in Fig.5.

Fig.5

Extrapolation of the energy gap to its bulk limit with use of the scaling function eq.(3.1). In this figure, solid circles, solid squares, solid triangles, open circles, open squares and open triangles represent $E_{\text{gap}}(N)/J$ for the set of parameters $(J_0/J, \delta)$, $(5.0, -0.129)$, $(4.5, -0.129)$, $(4.0, -0.128)$, $(3.5, -0.123)$, $(3.0, -0.116)$ and $(2.5, -0.104)$, respectively.

Fig.6

δ -dependence of the inter-chain spin-spin correlation functions, $\omega_{\frac{1}{2}\text{-}\frac{1}{2}}$ (solid circle), $\omega_{1\text{-}\frac{1}{2}}$ (solid square) and $\omega_{1\text{-}1}$ (solid triangle) for $J_0/J = 5.0$ and $N = 16$. Broken lines in left hand side of

this figure are indicating exact values taken by $\omega_{1-\frac{1}{2}}$, $\omega_{\frac{1}{2}-\frac{1}{2}}$ and ω_{1-1} in the dimer state from top to bottom. Broken lines in right hand side are indicating exact values taken by $\omega_{\frac{1}{2}-\frac{1}{2}}$, $\omega_{1-\frac{1}{2}}$ and ω_{1-1} in the VBS state from top to bottom.

Fig.7

δ -dependence of the inter-chain spin-spin correlation functions, $\omega_{\frac{1}{2}-\frac{1}{2}}$ (solid circle), $\omega_{1-\frac{1}{2}}$ (solid square) and ω_{1-1} (solid triangle) for $J_0/J = 1.5$ and $N = 16$. Broken lines in this figure has similar meanings to those in Fig.6.

Fig.8

δ -dependence of the energy gap for $N = 8$ (solid circle), $N = 12$ (solid square) and $N = 16$ (solid triangle), in the case of $J_0/J = 1.5$. The indicated value of δ_f , 0.58310, in this figure is that for $N = 16$.

Fig.9

Phase diagram for the ground state of the alternating spin ladder. Solid squares denote the transition points between the ferrimagnetic phase and the singlet phase. Solid circles in the singlet phase denote the transition points with vanishing an energy gap. Open circles indicate the points at which the energy gap between the two singlet phases take minimum values. Solid lines and a broken line are drawn for a guide to eyes. On the dot-dashed line, the dimer state becomes the exact ground state of the alternating spin ladder.
